ABSTRACT

The ‘within-season’ module of the Weed Manager decision support system (DSS) predicts the effect of twelve UK arable weeds on winter wheat yields and profitability. The model and decision algorithm that underpin the DSS are described and their performance discussed. The model comprises: (i) seedling germination and emergence, (ii) early growth, (iii) phenological development, (iv) herbicide and cultivation effects and (v) crop yield loss. Crop and weed emergence are predicted from the timing and method of cultivation, species biology, and the weather. Wheat and weeds compete for resources, and yield losses are predicted from their relative leaf area at canopy closure. Herbicides and cultural control methods reduce weed green area index, improving crop yield. A decision algorithm identifies economically successful weed management strategies based on model output. The output of the Weed Manager model and decision algorithm was extensively validated by experts, who confirmed the predicted responses to herbicide application were sufficiently accurate for practical use. Limited independent data were also used in the validation. The development of the module required integrating novel and existing approaches for simulating weed seedling establishment, plant development and decision algorithm design. Combining these within Weed Manager created a framework suitable for commercial use.

Keywords: Emergence pattern, weed development, weed competition

1. Introduction

Decisions on weed control in winter wheat (*Triticum aestivum L.*) should be a trade-off between economic impact of weeds and control cost. Developing EU legislation (Sustainable Use Directive) is likely to require that pesticide use should be based on a defined need for treatment (CRD, 2009a). The problem of control is complex because weed population and growth varies between sites and years. Generally, weeds are controlled using a combination of cultivations and herbicides. Cultivations can be used to kill emerged weeds pre- or post-drilling or to stimulate a flush of weeds prior to drilling. Herbicide use is even more complex with many commercial products available. Each product targets a subset of weed species with dose and timing affecting control. Products may be applied in mixture and/or sequence, in some cases with synergistic (or antagonistic) effects. Additionally, each herbicide has legal restrictions which limit use to certain times, doses and tank mixtures.

Sustainable weed management requires detailed understanding of weed populations, their effect on yield and methods of control. Simulation models can facilitate this understanding by combining expert knowledge with experimental data and by providing the ability to extrapolate to other years and sites. Here we describe a model, which estimates weed induced yield loss in a winter wheat crop, and its associated decision algorithm. The model simulates the impact of weed control strategies on weed and crop green area index (GAI), which in turn affects crop yield. The objective of the decision algorithm is to produce a list of alternative control strategies that maximise economic margin over weed control costs.

Empirical models have been used to relate crop yield loss to weed density (Cousens, 1985; Pannel et al., 2004) or to early relative leaf areas of weeds and crop (Kropff et al., 1995; van Acker et al., 1997). More complex ecophysiological models have also been developed, which mechanistically simulate competition (Kropff and van Laar, 1993). The model presented in this paper comprises an ecophysiological growth and development model, and an

empirical yield loss model. Where possible, established models were used to simulate the different processes, but it was also necessary to develop new approaches. For example, herbicide efficacy depends on weed growth stage (GS). Crop GSs are also needed to accommodate pesticide application restrictions, so models were required to predict phenological development of both wheat and weeds. Additionally, because the effectiveness of herbicides changes with weed growth stage it was very important to simulate the protracted emergence time of each weed species so that on any day a weed species is represented by cohorts at a realistic range of growth stages. Without these the effect of herbicides would be poorly estimated (Wiles et al., 1996).

Simulation models permit the investigation of many alternative weed control scenarios but the main focus of the presented models is to identify strategies that maximise economic margin because this is the primary interest of users. An exhaustive search of all alternatives would be impractical because the search space is large. It is better to use an optimisation algorithm. Many techniques have been developed, such as the genetic algorithm used by Parsons and TeBeest (2004) to optimise winter wheat disease control, or dynamic programming used by Benjamin et al. (2009) to optimise rotational weed control. In our case, the structure of the model and herbicide data meant the most practical approach was to develop an efficient searching strategy based on expert knowledge of weed control, the form of the model, and herbicide and cultivation data. The decision algorithm typically needs to run the model thousands of times, and so throughout the model development we guarded against unnecessary complexity.

The model and decision algorithm described here were developed for the "Weed Manager" decision support system (DSS) (Parsons et al. 2009). This is the first DSS to focus on weed management in UK winter wheat, although cognizance was taken of other weed DSSs (Wiles et al. 1996; Wilkerson et al., 2002; Berti et al., 2003; Rydahl, 2004; Pannell et

al., 2004). All approach the problem in different ways depending on their scientific background. Weed Manager was designed for farmers and advisors to investigate their own weed control strategies. Through a graphical user interface (GUI) the user is able to explore the impact of their strategies on economic margin or receive a suggested range of treatments. Weed Manager comprises a within-season module and a rotational module, which simulates weed control over a rotation (Benjamin et al., 2009). The within-season module is designed so that it can be integrated with the rotational module. This is so that factors affecting the long term management of the weed seedbank (essential in any prudent weed control strategy) can be taken into account when planning weed control for the current season. We return to this point in the discussion but throughout the description of our methods we focus on optimising the economic margin of the current crop. Weed Manager is part of ArableDS (Parsons et al., 2004) which is a suite of arable crop DSSs and encyclopaedias. This infrastructure provides the modules with information on pesticide cost, efficacy, mixture information and usage restrictions. It contains local weather and farm data, enabling simulations to be site specific. Copies of the program for Microsoft Windows® are available through www.weedmanager.co.uk, or from the authors.

In this paper, we describe the within-season model and decision algorithm for the within-season module of Weed Manager, and explore its performance. We parameterise the models and test them against independent data. Parameters were found for the following weeds; *Alopecurus myosuroides* Huds. (black-grass), *Stellaria media* (L.) Vill. (chickweed), *Galium aparine* L. (cleavers), *Avena fatua* L. (wild-oat), *Anisantha sterilis* (L.) Nevski (barren brome), *Lolium multiflorum* Lam. (Italian ryegrass), *Poa annua* L. (annual meadow-grass), *Chenopodium album* L. (fat hen), *Papaver rhoeas* L. (common poppy) and *Polygonum aviculare* L. (knotgrass), volunteer winter oilseed rape (*Brassica napus* L. ssp. *oleifera*) and volunteer field beans (*Vicia faba L.*).

2. Yield loss model

2.1 Overview of model structure

The model estimates weed induced yield loss in winter wheat for any given weed control scenario, and comprises five sub-models: (i) seedling germination and emergence, (ii) early growth, (iii) phenological development, (iv) herbicide and cultivation effects and (v) crop yield loss. Jointly, they simulate the growth and interaction of winter wheat and arable weeds producing an estimate of the proportional yield loss (Fig. 1).

The starting point for the weed growth simulation is an estimate of the seedbank. This is calculated from the anticipated weed density in the absence of weed control. Users provide this weed plant density by choosing one of four, species-dependent, density ranges. These anticipated densities are used to estimate the initial seedbank by back calculation, which includes adjustments to account for the influence of cultivation practices already carried out (or planned). The calculation of the proportion of seeds that emerge under given cultivation sequences is described in Benjamin et al. (2009).

Seedling emergence is influenced by species, temperature, water, and seasonal changes in dormancy, which interact with seedbed preparation (Forcella, 1998; Finch-Savage et al. 1998). Crop emergence and growth are simulated as a single cohort of seedling emergence at the user defined plant density (plants m^{-2}). Weed species have a more protracted emergence, which is modelled as a function of hydrothermal time (Finch-Savage et al., 1998). Here we captured this variation by simulating eight cohorts emerging over a period of time.

The simulation estimates daily growth stage (GS) and green area index (GAI) of the crop and weeds. This continues until the sum of the individual GAIs exceeds 0.75. This moment is defined as canopy closure. The ratio of the GAI of an individual weed species to the GAI of the crop and weeds at canopy closure is used to estimate the crop yield loss due to

that species (Kropff et al., 1995). The total weed induced yield loss is the sum of the yield losses attributed to each individual species. No competition between weed species is assumed, which is a reasonable for most commercial conditions; and also makes the predictions 'conservative', over- rather than under-estimating yield losses.

The effect of using herbicides and cultivations on yield loss is modelled by reducing the untreated GAI (calculated at canopy closure) for each weed. The size of the reduction depends on the product used, the dose and the weed cohort GS at the time of application.

As it is not feasible to predict crop yield without taking into account numerous site specific factors that were beyond the scope of the project, we ask the user to provide an estimate of yield in weed free conditions. Yield loss is calculated by scaling this value by the model estimate of proportional yield loss.

In the following sections we describe the model in more detail.

2.2 Climate and astronomical data

The weeds and wheat emerge and grow as a function of daily weather variables and day length. The weather variables, which are provided by the ArableDS environment, are maximum and minimum temperatures, radiation, rainfall and evapotranspiration. The emergence model uses temperature, rainfall, evapotranspiration and photoperiod. The weed and crop growth is modelled using radiation and temperature (as detailed below). Calculation of photoperiod uses the ASTRO procedure and is based on time of year and latitude (Kropff and van Laar, 1993). Users can include their own weather data, or the system will provide data from the nearest national meteorological station.

172 *2.3 Seedling emergence*

173

174 Our approach assumes the seedling emergence pattern is described by the logistic
175 Equation (1) given as a function of "emergence-day-degrees" accumulated after the initiation
176 of seedling emergence (the "emergence trigger" – see below)

177 $$n_s(t) = 1/\left(1+\exp\left(-\beta\left(\sum_{x=t_d}^{t} D_s(x) - \delta\right)\right)\right) \quad (1)$$

178 where $n_s(t)$ is the proportion of seedlings that have emerged, t is day number, t_d is the
179 emergence trigger day, δ and β are species-dependent parameters, and D_s (t) is the
180 emergence day-degrees on day t. The variable D_s is defined

181 $$D_s(t) = T_d(t)\, f_m(t)\, f_d(t) \quad (2)$$

182 where T_d is the mean temperature above base (0ºC), f_m is the moisture factor and f_d is the
183 dormancy factor (Forcella, 1998).

184 The emergence trigger is defined either as harvest date of the previous crop or the date
185 of ploughing, if it has occurred. This is based on the assumption that ploughing buries and
186 destroys seeds that have germinated and seedlings that have emerged, but brings another set
187 of seeds to the surface, which start to emerge. The model assumes that the number of seeds
188 being brought to the surface will be similar to the number buried. This simplifying
189 assumption is made in the absence of field specific data on the distribution of seeds in the soil
190 profile. Non-inversion cultivations have a less extreme effect on seed distribution in the soil
191 and so the emergence trigger of harvest date is retained where these cultivations are used.

192

193 *2.3.1 Soil moisture factor*

194 This assumes that soil moisture content is between the wilting point and field capacity.
195 Allen et al. (1998) reported that the difference in moisture content between these points was

196 up to 0.2 m^3 m^{-3} for loams and clays. The model considers the top 100 mm, within which
197 germination occurs, and assumes the soil is at wilting point at the emergence trigger. We
198 make this assumption because the trigger is either harvest or ploughing, which are typically
199 conducted in dry weather and the model is dealing with the layer of soil that dries most
200 rapidly. The model accumulates the difference between rainfall and potential
201 evapotranspiration (mm), constrained within the range 0 (wilting point) to 20 mm (field
202 capacity). The soil moisture factor f_m is 1.0 if the soil moisture value is greater than 5mm,
203 otherwise it is 0.0.
204
205 *2.3.2 Dormancy factor*
206 The dormancy factor, f_d, is a species-dependent function of the day of the year in the
207 range 0 – 1. To define the dormancy factor, the numbers of seedlings established each month
208 were taken from Mortimer (1990) (*A. myosuroides*, *S. media*, *G. aparine*, *A. fatua*, *P. annua*,
209 *C. album*, *P. rhoeas* and *P. aviculare*) and Froud-Williams (1983) (*A. sterilis*). *Lolium*
210 *multiflorum* was assumed to have the same dormancy characteristics as *A. sterilis*, whilst *B.*
211 *napus* and *V. faba* have no dormancy. For each species, the number emerging each month
212 was expressed as a proportion of the total number of seedlings emerging per year. This
213 emergence pattern is the result of all of the factors in Equation (1), so several simplifying
214 assumptions were required to estimate the dormancy factor. The seasonal temperature and soil
215 moisture cycles were not published for the Froud-Williams (1983) and Mortimer (1990) data,
216 so these were accounted for by standardising the emergence of each species using *P. annua*.
217 This has no seasonally affected dormancy, so its monthly emergence pattern can be attributed
218 entirely to seasonal changes in soil temperature and soil moisture. For each month, the ratio of
219 emergence of *P. annua* in July (the month with the greatest emergence) to the monthly
220 emergence was taken as a weighting factor applied to the monthly proportional emergence of

221 other weed species. A cubic polynomial was fitted to these values for each species and the
222 slope of this cubic polynomial for any day of the year was scaled to lie in the range [0, 1], to
223 define the dormancy function
224
225 *2.3.3 Parameterising the emergence pattern equation*
226 Seedling emergence counts for winter wheat, *A. myosuroides*, *G. aparine* and *S.*
227 *media* had been recorded at six sites, in three seasons, in a research project reported by Ingle
228 et al. (1997) approximately weekly for 100 days after sowing, along with daily maximum and
229 minimum temperatures. The drilling dates were late September or early October in all cases.
230 The daily temperature, precipitation and evapotranspiration needed to calculate accumulated
231 emergence-day-degrees for the Ingle et al. (1997) data were provided by J. Storkey (personal
232 communication). Equation (1) was fitted to each of the three species included in the 'Ingle'
233 experiments separately using FITCURVE (Genstat, 2002) (Table 1). The range of
234 temperatures during the experimental period was not sufficiently broad to allow the day-
235 degrees base temperature to be estimated accurately, and so it was assumed to be 0^{o}C
236 (estimated from Finch-Savage et al. (1998)). The agreement between observed and fitted
237 data was close (86, 88, 85 and 82% variance accounted for in adjusted R^2 for *A. myosuroides*,
238 *S. media*, *G. aparine* and wheat, respectively). The data for *A. myosuroides* are presented in
239 Fig. 2. In the absence of species specific data for the other weed species, emergence was
240 extrapolated from the behaviour of these three; for example the grass weeds *L. multiflorum*, *A.*
241 *sterilis* and *P. annua* followed *A. myosuroides*.
242
243 *2.3.4 Implementing emergence patterns in the model*
244 The model of emergence given by Equation (1) estimates the accumulated daily weed
245 seedling emergence. To model the subsequent development of each seedling would make the

model run time unacceptably long. Therefore we simplified the method whilst still retaining the qualitative nature of the emergence patterns. For wheat, seedlings are assumed to emerge δ emergence-day-degrees after sowing. Weed emergence is simulated over a spread of time by dividing the emergence period of each weed species into eight cohorts of equal density. Eight was judged to be the lowest number of cohorts that adequately captured the period of emergence. The number of seedlings in each cohort is calculated by dividing the expected number by the number of cohorts that emerge after drilling.

The simulation accounts for seedbed preparation stimulating the emergence of weeds. In all preparation methods one cohort germinates at drilling and emerges 80 emergence-day-degrees later (Finch-Savage et al. 1998). The other seven cohorts germinate at specified intervals from the emergence-trigger (based on the theoretical emergence pattern above).

The accumulated emergence-day-degrees, $H_e(i)$, between the emergence-trigger and emergence date for each cohort (i = 2, …8) is defined by rearranging Equation (1) to give

$$H_e(i) = \delta - \frac{1}{\beta}\ln\left(\frac{1-f(i-1)}{f(i-1)}\right) \quad (3)$$

where for direct drill $f(i) = (0.125, 0.25, 0.375, 0.5, 0.625, 0.75\ 0.875)$. For other cultivation sequences (ploughing and non-inversion cultivation) the soil disturbance breaks the dormancy of some seeds bringing forward germination of cohorts i = 3,…,8. For simplicity we assume that cohort 3 emerges at the same time as cohort 2 and cohorts 4 – 8 emerge when cohorts 3 – 7 would under a direct drill scenario, thus $f(i) = (0.125, 0.125, 0.25, 0.375, 0.5, 0.625, 0.75)$.

2.4 Phenological development

Herbicide efficacy depends on weed GS, and pesticide application restrictions are often given in terms of the GS of the crop. Although growth was only simulated up to canopy closure, herbicides could be applied throughout the season from drilling to harvest. Therefore

we needed to model the phenological development of weeds and crop up until maturity. We used the Zadoks GS scale for graminaceous weeds and wheat (Zadoks et al., 1974). Growth stages from GS30 to maturity (GS92) are defined by Milne et al. (2003). The beginning of germination (H_g) (GS0), is defined in emergence-day-degrees by

$$H_g(i) = \max\left(H_e(i) - 80.0, 0\right) \quad (4)$$

Between germination and the day of emergence (t_s) the GS (Z) on day t is

$$Z = 10\sum_{s=t_g}^{t} D(s) / \sum_{s=t_g}^{t_s} D(s) \quad (5)$$

where D is day-degrees. After emergence, $Z = 10$ until the first leaf is formed. A new leaf appears when the accumulated day degrees from the appearance of the previous leaf exceed the species specific phyllochron. The value of Z increases from 11 to 14 with the appearance of first to fourth leaf. Once four leaves have been produced tillering commences (GS21–29). Tillers appear every 100 day ^{o}C (based on expert opinion) until main stem extension (GS 30) is initiated.

A similar approach is taken for broad-leaved weeds with GSs after emergence based on the number of leaves on the entire plant. Unlike graminaceous weeds, branching (the equivalent of tillering) does not directly affect the GS code. The number of leaves produced per phyllochron may be more than one (e.g. a pair of opposite leaves). Flower buds are produced when a species-specific number of day degrees have accumulated.

2.5 Growth and competition

The growth of each species from emergence to canopy closure is simulated using the ecophysiological model INTERCOM (Kropff and van Laar, 1993). The height and leaf area of the crop and weeds determine their daily light interception, and the consequent increase in dry matter is partitioned to the different plant organs. The increase in GAI is calculated from

295 the specific leaf area. The initial GAI of each weed cohort and the crop is based on the green
296 area per seedling at the time of full hypocotyl or cotyledon expansion and density. Where this
297 initial seedling green area is not known the value is estimated as the product of: for grasses,
298 the green area per *A. myosuroides* seedling (35 mm^2) and the ratio of the species seed weight
299 to the seed weight of *A. myosuroides* (1.1 mg); and for broad-leaved species, the product of
300 the green area per *S. media* seedling (31 mm^2) and the ratio of the species seed weight to the
301 seed weight of *S. media* (0.8 mg) (Storkey, 2001).

302 Photosynthate supply or temperature can limit plant growth (Benjamin and Park,
303 2007). To estimate which of these is most limiting, daily increase in GAI is calculated in two
304 ways: firstly, from the above calculations of dry matter (based on INTERCOM) and secondly
305 from a simple temperature based exponential model (Storkey and Cussans, 2000). The daily
306 increase in GAI is taken as the lower of the two values. For weed species that are not winter
307 hardy, there is a daily loss of 90% of total GAI whenever the minimum air temperature falls
308 below -5^{o}C. This is necessary to ensure the model does not predict yield loss from autumn-
309 emerging weeds that do not survive British winters.

310 The simulation commences on the date of emergence of the first cohort of the weed or
311 the crop (which ever is the earliest), and further weed cohorts are included as the simulation
312 proceeds to canopy closure (GAI = 0.75).

313

314 *2.6 Crop yield loss*

315

316 The yield loss (t ha^{-1}) associated with a weed species is

317 $$Y_L = \frac{YqL_w}{1+L_w(q-1)} \quad (6)$$

318 where Y is crop yield (t ha^{-1}) in weed-free conditions, q is the weed species dependent
319 damage coefficient. L_w is

$$L_w = \frac{GAI_w}{GAI_w + GAI_c} \quad (7)$$

(Kropff et al., 1995), where GAI_w is the GAI of weed *w* and GAI_c is the crop GAI at canopy closure. Values for *q* were derived from our own experiments and from the published literature and were 2.55 for *A. myosuroides*, 0.6 for *S media* and 23.9 for *G. aparine*. The weeds are assumed to act independently of one another. That is to say, it is assumed that one weed's growth does not suffer from the competitive effects of another. Therefore, the total weed-induced yield loss is calculated as the sum of the yield losses attributed to each weed species. The total yield loss is not allowed to exceed the weed-free crop yield.

2.7 Weed control (*herbicide and cultivation effects*)

The effect of using herbicides and/or mechanical cultivations on yield loss is modelled by reducing the untreated GAI of each weed cohort calculated at canopy closure. The reduction depends on the product (the term "product" includes cultivations and herbicides) efficacy. The efficacy *e* of a product against a weed cohort will depend on the weed species, the dose applied and the GS of the cohort at the time of application. The model of herbicide control is not mechanistic. The effect of each weed control measure, be it conducted before or after canopy closure, is reflected in a reduction in GAI at canopy closure. The effect of timing of control on yield is implicit in the efficacy. In the majority of cases, late application will result in reduced efficacy. Therefore, the model will favour early treatment, but there will be a bias towards some under-prediction of yield loss at later applications because the model does not fully account for greater duration of weed competition.

The product efficacy data are stored in a database which is accessed by the model. They take a similar form to herbicide label data, with efficacies given for fixed doses against

345 weed species at consecutive GS ranges. For grass weeds the Zadoks GS ranges are $0-7$,
346 $8-10$, $11-13$, $14-21$, $22-29$, $30-31$, $32-39$, $40-45$ and $46-93$; for broad-leaved
347 weeds the ranges are pre-emergence, pre-emergence – cotyledons, cotyledons – 2 leaves,
348 $2-4$, $4-6$, $6-8$, and 8 leaves – flowering. The efficacies are categorised as resistant,
349 moderately resistant, moderately sensitive, sensitive and complete kill, mapping to e=0.01,
350 0.51, 0.76, 0.91 and 1.0, respectively. These values are similar to those published by CRD
351 (2009b) for herbicide registration. Published and unpublished (but manufacturer supported)
352 product information was used to assign efficacies to each weed species, GS and product
353 combination (D. H. K. Davies, personal communication).

354 If a single product is applied to a weed, the treated GAI of the *j*th cohort is obtained by
355 multiplying the untreated GAI by the product efficacy, *e.* If a product mixture is applied it is
356 treated in one of two ways. If the product mixture (including product plus adjuvant) is known
357 to be synergistic then the combination is treated as a pseudo product with its own efficacy
358 data. Otherwise the combined efficacy *E*, of products either in mixture, sequence or both is
359 calculated by:

360 $$E = 1 - \prod_{i=1}^{n} (1 - e_i) \qquad (8)$$

361 where e_i is the efficacy of the i^{th} product against the weed cohort at the GS at which it was
362 applied, and *n* is the number of products in the control programme.

363

364 *2.8 Variability*

365

366 There is always some uncertainty in prediction. This is due to, among other factors,
367 error in the seedbank estimation and unknown future weather. Therefore the model prediction
368 of weed induced yield loss is presented to the user as a range of values, indicating the

variability associated with the prediction. We assume that most variability arises from uncertainty associated with estimating weed and crop density. The users define the weed and crop populations from a set of density ranges. The mean expected yield loss is calculated using the means of the density ranges for weed and crop. The greatest/least possible yield loss is calculated using the lower/upper bound of the crop density and the upper/lower bound of the weed density.

3. The decision algorithm

The decision algorithm suggests a list of the most robust weed control strategies for a given scenario. The scenario comprises weather, site, sowing date, weed list and any cultivations and herbicides applied to date in the season.

The algorithm incorporates rules on cultivation practices and timing and dose of herbicides, ensuring only legally acceptable and practical strategies are suggested. These rules are either "restrictions data", which are part of the legal registration process, or "recommendations for effective use" and are defined by the herbicide manufacturers and marketers. Most are on the product label. Restrictions and recommendations data contain "do not mix" rules prohibiting dangerous or antagonistic tank mixes. There are also restrictions on pre-sowing sequences of cultivations to ensure an appropriately prepared seedbed. All of the above rules are contained in the ArableDS and Weed Manager databases. Each cultivation and herbicide programme is validated against the rules.

The decision algorithm aims to maximise the margin, *M*, over weed control costs

$$M = (Y - Y_L)g - P_H - P_C \quad (9)$$

where Y is the expected weed-free crop yield, Y_L is the weed induced yield loss, g is the grain price, P_H is the cost of the herbicide programme and P_c is the cost of the cultivation programme.

To ensure the algorithm reaches a solution within a few minutes (a time acceptable to users) the slowest parts of the model are run as few times as possible (otherwise reaching a solution could take several hours). These are calculating emergence patterns and growth to canopy closure. The emergence pattern depends on the pre–sowing cultivation programme (see Fig. 1) and once the pattern is established subsequent weed control treatments have no effect on GS estimates. The decision algorithm exploits this by minimising the number of cultivation combinations to be tested and calculating the growth stages for each only once.

If the sowing date is prior to the current date, then it follows that the pre-sowing cultivation programme has been defined by the user. Otherwise, the suggested control strategies include pre-sowing cultivations. To minimise the number of cultivation combinations tested, the system selects up to three pre-sowing cultivation programmes (described below). For each cultivation programme the model is run to canopy closure and the untreated GAIs are stored. A list of valid herbicide and post-sowing cultivation programmes is generated (described below) and their effects on the weed GAI are calculated using Equation (8). These are applied to the untreated GAI and the revised GAIs are used to calculate the weed induced yield loss (Equation 6) and margin (Equation 9). The weed control programmes are sorted to remove poor solutions and repetitions of very similar programmes and the top 20 are presented to the user. This produces a short list of diverse solutions.

3.1 Defining the pre-sowing cultivation programme

The system contains data for eight pre-sowing cultivations (mouldboard plough, spring tine, harrows, rollers, powered harrows, heavy tines, discs, heavy disc) as well as drilling and direct drilling. These are used in combination to prepare the seed bed and sow the wheat. We term such a series of activities a pre-sowing cultivation programme. If the current date is before sowing and the user has not identified any preferred options, a maximum of three pre-sowing cultivation programmes are selected: nominally non-inversion, ploughing and direct drill. The non-inversion sequence starts with the primary cultivation (1) on the day after the current date and follows this with secondary cultivation (2) on the day before drilling. The first cultivation stimulates weed emergence and the second removes many of those that have emerged. Hence the maximum amount of time is left between cultivations (Pannell et al., 2004). This sequence is run for all valid combinations of cultivations 1 and 2 (tested against database information on timing and which combinations of cultivations acceptably prepare the seedbed). The cultivation plan that gives the highest margin defines the non-inversion programme. For ploughing, cultivation 1 is mouldboard plough two days before drilling (removing most of the germinated weeds) and cultivation 2 is harrowing the next day. The direct drill programme sows the crop without any pre-sowing soil cultivations. If primary cultivations have already been done these effectively define cultivation 1 and only cultivation 2 is selected by the algorithm. In this case, the model is run with all valid options for cultivation 2 and the one that gives the highest margin is selected. As stated above this method results in a maximum of three different pre-sowing cultivation programmes, which are taken forward and investigated with valid herbicide combinations as described below. To ensure the optimisation reaches a solution in a few minutes it was necessary to define the timings for the non-inversion and ploughing sequences. These were based on one of several possible practical approaches. The chosen timings will not be the best in all scenarios, but will

produce robust solutions. The users are still able to define other sequences that can be taken forward to the next step of the optimisation should they wish to.

3.2 Defining the herbicide and post-sowing cultivation programme

There are many herbicide products available and users can, if they wish, limit the herbicide selection by only including products that are available on their farms. The season is split into four consecutive treatment periods; "pre-emergence" (before wheat GS 9), "autumn" (between GS 9 and 1st January), "spring" (between 1st January and GS 90) and "desiccant" (period after GS 90). In each period there is only one application of product/mixtures. In each period the timing for each product/mixture that gives the least yield loss is evaluated and saved to a list. The lists are reduced by removing products/mixtures that have lower efficacy against the target weeds than cheaper products/mixtures in the list. All valid combinations of the reduced lists are evaluated forming a list of "viable programmes", and up to 20 of the best performing programmes are presented to the user (as described above).

4. Model validation

Some experimental data were available but these were insufficient to validate the model and decision algorithm fully, so much of the validation was done using expert agronomic opinion. Field and research weed scientists associated with the project but not directly involved in model development, examined a wide range of outcomes from the model, with the different weed species, cultivation practices and herbicides, and assessed whether the predictions were agronomically sound. This resulted in many improvements. Several independent data sets from the UK were also found that could be used for partial validation.

These included published papers and unpublished research carried out by consortium members. The work focused on assessing predicted crop yields arising from uncontrolled infestations of target weeds, as these responses were more likely to identify problems with the predictions but some herbicide performance data were also identified.

Independent data were found for *S. media*, *G. aparine, A. fatua* and *A. myosuroides*. As far as possible, the published agronomic data were used as the basis for the predictions. As these data spanned several decades, we were unable to access the associated weather data. Consequently, we used standardised ArableDS regional climatic data (Parsons et al., 2009).

4.1 Predicting yield losses from uncontrolled weeds

4.1.1 Broad-leaved weeds (S. media *and* G. aparine)

Wheat yield responses to *S. media* were determined from three experiments (Lutman unpublished data, 2006). The model consistently over-estimated the crop response to competition from this weed, especially at higher densities at Rothamsted (Table 2). The two experiments on *G. aparine* showed contrasting yield responses (Wright and Wilson, 1992). In trial Bristol 1, there was little yield loss from the weed, whilst the model predicted considerable losses. Wright and Wilson commented on the surprising lack of yield loss from the *G. aparine* and attributed this to a summer drought that reduced its competitive effect. In contrast, in Bristol 2 the yield losses were higher and within the range the model predicted.

4.1.2 Grass weeds (A. fatua *and* A. myosuroides)

Two experiments (Oxford 1 and 2) measured the response of winter wheat to competition from *A. myosuroides* (Wilson, 1980). In Oxford 1, predicted yield loss was close to the actual response (Table 2), whilst in Oxford 2 it was less than predicted. Wilson

attributes the low yield loss in Oxford 2 to the 'profuse late summer vigour of the wheat'. In the four *A. fatua* experiments, the model was within 0.6 t ha^{-1} in two experiments (Bristol 4 and Oxford 4), underestimated the response in Bristol 3 and overestimated it in Oxford 3 (Wilson et al., 1990; Wright and Wilson, 1992). The two Oxford data sets were from the same experiment, but with differing crop densities. The results suggest the model was overreacting to the low crop density in Oxford 3 and if it is increased by one band (i.e. from 100–149 to 150–199 wheat plants m^{-2}) the predictions are much closer to the actual yields. The more pronounced yield losses in the Bristol 3 experiment, which was done in the same season as Bristol 1, may also be associated with the summer drought, as the crop was unable to compensate for the early competition exerted by the *A. fatua*.

4.2 Evaluation of predicted crop yield responses to the control of A.myosuroides

The previously discussed experiments on *A. myosuroides* (Wilson, 1980) also included results from November applications of isoproturon. These achieved good weed control and yields increased (Table 3). Predictions for Oxford 1 were within 0.7 t ha^{-1} of the observed yield and those for Oxford 2 continued to over-estimate yield losses (as discussed above).

A third experiment evaluated herbicidal control of metabolic resistant *A. myosuroides* at ADAS (Boxworth). It compared three treatments (classed as early, late and full) and an untreated control. The model under-estimated the yield loss in the absence of weed control, but predictions improved with increased control. The prediction with the least effective (early) treatment was least accurate, reflecting the under-estimate of the response of the untreated.

5. Discussion

The model and decision algorithm were developed for the Weed Manager DSS, and this purpose determined their design. It meant achieving a balance between being sufficiently complex so that key parts of the biological mechanism were described, parsimony and model run times of a few seconds (important for the decision algorithm). Established models were used where possible. For example, yield loss was based on well-established models relating yield loss to relative crop and leaf area (Kropff et al., 1995) and seedling emergence was based on hydrothermal models of seedling establishment (Finch-Savage et al., 1998; Forcella, 1998). However, it was also necessary to develop new modelling approaches to certain aspects of weed development: for example, the effect of seed dormancy, spread of weed seedling emergence, and growth stage progression. Where sufficient data were not available to define parameters for the novel parts of the model, expert opinion and logical extrapolation were used. In particular there were insufficient data to estimate the day-degree requirement for seed germination and seedling emergence or their base temperatures and, for some species, initial seedling green area. Similarly, the stimulation of seedling emergence due to soil disturbance was simulated by advancing a cohort to be a specified thermal time after seedbed preparation. Since the time of development of the DSS new data have become available (J. Storkey, personal communication) and so it may now be possible to estimate these parameters more accurately. Our concerns to minimise runtime led to the pragmatic decision to base estimates of yield loss on the relative calculated GAI of the crop and the weed at canopy closure. It would have been biologically sounder to incorporate the impact of the time of control on weed competition more mechanistically, but with computer power at the time of development was impractical. Increased computer power in the future may provide opportunities to re-evaluate this. Despite these shortcomings, expert assessment of the models concluded that they performed sufficiently well and were fit for purpose.

For legal liability reasons, the system uses only approved recommended rates of herbicide products. Therefore, dose flexibility is not as great as in some other weed DSSs (e.g. Rydahl, 2004). An advantage of our method is that herbicide parameter updates are straightforward, as they can be extracted from labels. However, this approach requires a large number of herbicide product parameters, unlike the more parsimonious approach of parameterising active ingredients (see Milne et al., 2007).

The decision algorithm also proved an unwitting critic of the model as, during the system development, it suggested mathematically correct, but biologically flawed solutions. This led to an improved description of biological mechanisms important to weed control, in particular, the need to account for the protracted emergence of weed species. The decision algorithm was tested by experts who concluded the results were sound (Parsons et al., 2009).

The field trials indicate that in the absence of weed control, the model tends to over-estimates yield losses from weeds. However, because of large variation in the data we are cautious with our conclusions. Taking into account the variability in the field data, yield losses were over-estimated in five trials, under-estimated in two and were reasonably accurate in four. The over-estimation mainly affected the *S. media* results and this systematic error requires attention. From a farming viewpoint, this over-estimation is a lesser error, as it is risk averse. In three of the 11 trials, extreme summer weather resulted in poor predictions of yield loss, as they had influenced the competitive characteristics of the species concerned. The drought in experiments B1 and B3 had had contrasting effects. It had reduced the competitive effect of *G. aparine*, as this late maturing species was unable to develop its normally highly competitive canopy in late summer. In contrast the drought increased the competitive impact of *A. fatua*, as this earlier maturing species was able to exert its full competitive impact on the crop, whilst the crop was unable to recover in the latter part of the summer. These issues highlight problems associated with predicting yield loss early in the

565 season, when variable weather events ensue. Weed Manager is designed to be run throughout
566 the season, with weather data and weed observation updates. Consequently, as the season
567 progresses, predictions should improve. The limited validations of herbicide performance
568 (Table 3) indicate that where weed control is high the model's predictive ability is better than
569 in the absence of control. This is encouraging because we would expect the variability in
570 response to herbicide treatment to reduce with increased control, and so should be more
571 accurate.

572 The within-season module discussed in this paper has been presented as a decision
573 support module that is concerned only with the current cropping season. This is often not the
574 most practical approach and weed control should ideally take a more long term view if the
575 weed seedbank is to be kept at a manageable level. This is the focus of the rotational module
576 (Benjamin et al 2009), which accompanies the within-season module in the Weed Manager
577 DSS. The two systems have been designed to be compatible. The long term module can be
578 used to estimate the percentage kill needed to keep a weed at a manageable level over a
579 rotation. The within-season module estimates the expected kill of each weed under a given
580 scenario and displays it to the user so that they can see if their targets have been met. In future
581 developments we plan that the user will be able to define a minimum percentage kill (for
582 example that suggested by the rotational system) that the optimisation algorithm must aim to
583 achieve. Solutions which do not achieve this target will be removed from the list of viable
584 programmes (described above).

585 Weed Manager was developed as a tactical DSS for farmers and advisors but also has
586 educational value, illustrating the complex interactions between weed biology, cultivation
587 practices and weed control. For example, the within-season module provides a valuable tool
588 to explore and illustrate the complex interactions between the range of development stages of
589 weeds, their competitive effects and vulnerability to control measures. Development is still

needed, to increase the number of weeds and to validate the results of the species currently included.
